Sample Problem Set
RSA Encryption

Public-Key Encryption and Digital Signatures

The ideas of *public-key encryption* and *digital signatures* were discovered only in 1976. But they already play a fundamental role as a way to achieve private communication in a world that relies increasingly upon digital information. Interestingly, the fact that there are fast algorithms for exponentiation and for testing prime numbers (sections 1.2.4–1.2.6 of the text) lies at the root of RSA—the most popular method for implementing public-key encryption. In this problem set you will implement a version of the RSA system. By doing so, you will gain experience with some algorithms that although simple, have immense practical importance.¹ Section 1 of this handout describes how the system works. Section 2 contains exercises that you should be prepared to discuss in tutorial. Section 3 contains background for the lab assignment, and section 4 is the actual lab assignment.

1. The RSA System

People have been using secret codes for thousands of years; for this reason it is surprising that in 1976, Whitfield Diffie and Martin Hellman at Stanford University discovered a major new conceptual approach to encryption and decryption; *public-key cryptography*.²

Cryptography systems are typically based on the notion of using *keys* for encryption and decryption. An *encryption key* specifies the method for converting the original message into an encoded form. A corresponding *decryption key* describes how to undo the encoding. In traditional cryptographic systems, the decryption key is identical to the encryption key, or can be readily derived from it. As a consequence, if you know how to *encrypt* messages with a particular key then you can easily *decrypt* messages that were encrypted with that key.

Diffie and Hellman's insight was to realize that there are cryptographic systems for which knowing the encryption key gives no help in decrypting messages; that is, for which there is no practical way to derive the decryption key from the encryption key. This is of immense practical importance. In traditional cryptographic systems, someone can send you coded messages only if the two of you share a secret key. Since anyone who learns that key would be able to decrypt the messages, keys must be carefully guarded and transmitted only under tight security. In Diffie and Hellman's system, you can tell your *encryption* key to anyone who wants to send you messages, and not worry about key security at all. For even if everyone in the world knew your encryption key, no one

¹This problem set was designed in 1987 by Ruth Shyu and Eric Grimson and revised in 1992 by David LaMacchia and Hal Abelson.

²W. Diffie and M. Hellman, "New directions in cryptography," *IEEE Transactions on Information Theory*, IT-22:6, 1976, pp 644–654.

could decrypt messages sent to you without knowing your *decryption key*, which you keep private to yourself. Diffie and Hellman called such a system a *public-key* cryptography system.

A few months after Diffie and Hellman announced their idea, Ronald Rivest, Adi Shamir, and Leonard Adelman at MIT discovered a workable method for implementing it. This *RSA cryptography system* has remained the most popular technique for public-key cryptography.

The theory behind RSA

RSA uses integers to represent groups of characters³ and uses special functions that transform integers to integers.

In the RSA scheme, you select two large prime numbers, p and q . You then define

$$n = pq \tag{1}$$

$$m = (p-1)(q-1). \tag{2}$$

You also select a number e , such that $\gcd(e, m) = 1$. Your *public key*, which you can advertise to the world, is the pair of numbers n and e . Anyone who wants to send you a message s (represented by an integer) encrypts it using the following *RSA transformation* defined by n and e :

encrypted message = s to the power of e , modulo n

or

$$S = (s^e) \bmod n.$$

If you receive an encrypted message S , you decrypt it by performing another RSA transformation with n and a special number d :

$s' =$ encrypted message to the power of d , modulo n

or

$$s' = (S^d) \bmod n.$$

The number d is chosen to have the property that $s = s'$ for every message s ,⁴ namely,

$$s = (s^e)^d \bmod n.$$

It can be shown that the number d that has this property is the one for which

$$de = 1 \bmod m \tag{3}$$

that is, for which d is the *multiplicative inverse* of e modulo m .⁵ It turns out that it is easy to compute d efficiently if you know e and $m = (p-1)(q-1)$.

³For example, the ASCII standard representation of a character is a 7-bit integer. In this problem set we will represent a block of four characters as a 28-bit integer ($0 \leq s < 2^{28}$) by concatenating the ASCII codes of the four characters.

⁴Actually, this is true only if $\gcd(s, n) = 1$. If n is the product of two large primes, then almost all messages $s < n$ will satisfy this.

⁵This is a basic result in number theory, we'll just ask you to take it on faith.

Thus, to generate a pair of RSA keys, you choose prime numbers p and q , compute $n = pq$, choose e , and use this to compute d . You publish the pair n and e as your public key, but keep d secret to yourself. People send you encrypted messages using the pair (n, e) . You decrypt these messages using the pair (n, d) .

The security of the RSA system is based on the fact that even if someone knows e and n , the most efficient way known for them to decrypt a message is to factor n to find p and q , then use these to compute m , then use e and m to compute d .

That is to say, cracking an RSA code is, as far as anyone knows, as difficult a computational problem as factoring n into its prime factors p times q . And although there has been a tremendous amount of research on factoring, factoring arbitrary large numbers is not a computationally feasible task. For example, factoring $n = pq$ where p and q are each 200-digit primes, even with the today's best factoring algorithms, would require running for more than 100 years on today's fastest supercomputers.⁶

Digital signatures; Encrypting and signing

In their 1976 paper, Diffie and Hellman suggested applying public-key encryption to solving another important problem of secure communication. The problem is this: suppose you want to send a message by electronic mail. How can people who receive the message be sure that it really comes from you—that it is not a forgery? What is required is some scheme for marking a message in a way that cannot be forged. Such a mark is called a *digital signature*.

Diffie and Hellman's suggestion was to proceed as follows: take the message and apply a publicly agreed upon *compression function* (also called a *hash function*) that transforms the message to a single, relatively small number. In general, there will be many messages that produce the same hash value. Now transform the hash value using your private key. The transformed hash value is your digital signature, which you transmit along with the message. Anyone who receives a message can authenticate the signature by transforming it using your *public key* and checking that this gives the same result as applying the compression function to the message.

The reason this scheme works is that anyone who wants to forge a message claiming to be from you must produce a number that, when transformed by your public key, matches the hash value. Anyone can compute the hash value, since the compression function is assumed to be public. But since you are assumed to be the only one who knows your private key, only you can produce the number which is transformed to the hash value by your public key. Trying to forge a digital signature is essentially the same task as trying to crack a public-key encrypted message.

An even cuter idea works as follows: Suppose Barbara wants to send George a signed message that only George will be able to read. She encrypts the message using George's public key. Then she signs the encrypted result using her own private key. When George receives a message that is supposed to be from Barbara, he first uses Barbara's public key to authenticate the signature, then decrypts the message using his own private key. Figure ?? gives an overview of the method.

⁶No one has actually proved that cracking an RSA code is as difficult a problem as factoring, but no other method for cracking these codes has been discovered. In addition, some computer scientists believe that it may be possible to prove that there can be no fast (e.g., logarithmic time) algorithms for factoring. Given the popularity of RSA,

Figure 1: Encryption with digital signature.

Notice what this accomplishes: George can be sure that only someone with Barbara’s private key could have sent the message. Barbara can be sure that only someone with George’s private key can read the message. This is accomplished without exchanging any secret information between George and Barbara. It’s this capacity for achieving secure communication without having to worry about exchanging secret keys that makes public-key cryptography such an important technique.

Implementing RSA

The primary thing we need in order to implement RSA is the fast exponentiation algorithm from section 1.2.6 of the text:

```
(define (expmod b e m)
  (cond ((zero? e) 1)
        ((even? e)
         (remainder (square (expmod b (/ e 2) m)) m))
        (else (remainder (* b (expmod b (- e 1) m)) m))))
```

We’ll assume that an RSA key is represented as a pair—modulus and exponent:

```
(define make-key cons)
(define key-modulus car)
(define key-exponent cdr)
```

The basic RSA transformation is then

```
(define (RSA-transform number key)
  (expmod number (key-exponent key) (key-modulus key)))
```

Generating prime numbers

To generate RSA keys, we first of all need a way to generate primes. The most straightforward way is to pick a random number in some desired range and start testing successive numbers from there until we find a prime. The following procedure starts searching at a randomly chosen integer between `start` and `start + range`:

```
(define (choose-prime smallest range)
  (let ((start (+ smallest (choose-random range))))
    (search-for-prime (if (even? start) (+ start 1) start))))

(define (search-for-prime guess)
  (if (fast-prime? guess 2)
      guess
      (search-for-prime (+ guess 2))))

(define choose-random
  ;; restriction of Scheme RANDOM primitive
  (let ((max-random-number (expt 10 18)))
    (lambda (n)
      (random (floor->exact (min n max-random-number))))))
```

The test for primality is the Fermat test, described in section 1.2.6:

the discovery of such an algorithm would result in a massive security breakdown for banks, businesses, and other organizations that use RSA.

```

(define (fermat-test n)
  (let ((a (choose-random n)))
    (= (expmod a n n) a)))

(define (fast-prime? n times)
  (cond ((zero? times) true)
        ((fermat-test n) (fast-prime? n (- times 1)))
        (else false)))

```

Generating RSA key pairs

Now we can generate a public RSA key and matching private key. We'll represent these as a pair:

```

(define make-key-pair cons)
(define key-pair-public car)
(define key-pair-private cdr)

```

The following procedure generates an RSA key pair. It picks primes p and q that are in the range from 2^{14} to 2^{15} so that $n = pq$ will be in the range 2^{28} to 2^{30} , which is large enough to encode four characters per number.⁷ After picking the primes, it computes n and m according to equations (1) and (2). It then chooses an exponent e and finds a number d that satisfies equation (3).

```

(define (generate-RSA-key-pair)
  (let ((size (expt 2 14)))
    (let ((p (choose-prime size size))
          (q (choose-prime size size)))
      (if (= p q) ;check that we haven't chosen the same prime twice
          (generate-RSA-key-pair) ;VERY unlikely)
      (let ((n (* p q))
            (m (* (- p 1) (- q 1))))
        (let ((e (select-exponent m)))
          (let ((d (invert-modulo e m)))
            (make-key-pair (make-key n e) (make-key n d))))))))

```

The exponent e can be any random number $0 < e < m$ with $\gcd(e, m) = 1$. The \gcd procedure is given in section 1.2.5 of the notes, but is actually a Scheme primitive.

```

(define (select-exponent m)
  (let ((try (choose-random m)))
    (if (= (gcd try m) 1) ;if gcd is not 1, then try again
        try
        (select-exponent m))))

```

Computing the multiplicative inverse

The number d required for the RSA key must satisfy

$$de = 1 \bmod m$$

⁷We're using such small values of n for this problem set because we want you to play around with cracking an RSA system. By starting with larger random numbers, you can use the same method to produce a system that really is secure.

Using the definition of equality modulo m , this means that d must satisfy

$$km + de = 1$$

where k is a (negative) integer. One can show that a solution to this equation exists if and only if $\gcd(e, m) = 1$. The following procedure generates the required value of d , assuming that we have another procedure available which, given two integers a and b , returns a pair of integers (x, y) such that $ax + by = 1$.⁸

```
(define (invert-modulo e m)
  (if (= (gcd e m) 1)
      (let ((y (cdr (solve-ax+by=1 m e))))
        (modulo y m)) ;take y modulo m, in case y was negative
      (error "gcd not 1" e m)))
```

Solving $ax + by = 1$ can be accomplished by a nice recursive trick that is closely related to the recursive GCD algorithm in section 1.2.5 of the text. Let q be the quotient of a by b , and let r be the remainder of a by b , so that

$$a = bq + r$$

Now (recursively) solve the equation

$$b\bar{x} + r\bar{y} = 1$$

and use \bar{x} and \bar{y} to generate x and y . We'll leave to you the details of how to write the actual procedure. (Ask in recitation.)

Encrypting and decrypting messages

Finally, to use RSA, we need a way to transform between strings of characters and numbers. The code for this problem set includes procedures `string->intlist` and `intlist->string` that convert between character strings and lists of integers. Each integer (between 0 and 2^{28}) encodes 4 successive characters from the message. If the number of characters is not a multiple of 4, the message is padded by appending spaces:

```
(string->intlist "This is a string.")
;Value: (242906196 69006496 245157985 217822450 67637294)

(intlist->string '(242906196 69006496 245157985 217822450 67637294))
;Value: "This is a string.  "
```

The code for these two procedures is included with the problem set code, but you are not responsible for it. You may want to look at it if you are interested in how character strings can be manipulated in Scheme.

To encrypt a message, we transform the message into a list of numbers and convert the list of numbers using the RSA process together with one key in the key pair.

```
(define (RSA-encrypt string key1)
  (RSA-convert-list (string->intlist string) key1))
```

⁸The Scheme primitive `modulo`, which we use to insure a positive result, is the same as `remainder`, except on negative arguments: `(remainder -12 7)` is -5 , while `(modulo -12 7)` is 2 . In general, `(modulo a b)` always has the same sign as b , while `(remainder a b)` always has the same sign as a .

You might guess that the right way to encode the list of numbers would be to encode each number in the list separately. But this doesn't work well. (See exercise 5 below.) Instead, we encrypt the first number, subtract that from the second number (modulo n) and encrypt the result, add that to the next number and encrypt the result, and so on, so that each number in the resulting encrypted list will depend upon all the previous numbers:

```
(define (RSA-convert-list intlist key)
  (let ((n (key-modulus key)))
    (define (convert l sum)
      (if (null? l)
          '()
          (let ((x (RSA-transform (modulo (- (car l) sum) n)
                                      key)))
            (cons x (convert (cdr l) x))))))
    (convert intlist 0)))
```

We'll leave it to you to implement the analogous `RSA-unconvert-list` procedure that undoes this transformation using the other key in the key pair. Then we have

```
(define (RSA-decrypt intlist key2)
  (intlist->string (RSA-unconvert-list intlist key2)))
```

Finally, to generate digital signatures for encrypted messages, we need a standard compression function. In this problem set, we'll simply add the integers modulo 2^{28} .⁹

```
(define (compress intlist)
  (define (add-loop l)
    (if (null? l)
        0
        (+ (car l) (add-loop (cdr l)))))
  (modulo (add-loop intlist) (expt 2 28)))
```

⁹In practice, people use more complicated compression schemes than this. You might want to think about why.

2. Exercises

Exercise 1: What is the difference between the following two ways of defining `choose-prime`?

```
(define (choose-prime smallest range)
  (search-for-prime (+ smallest (choose-random range))))

(define choose-prime
  (lambda (smallest range)
    (search-for-prime (+ smallest (choose-random range)))))
```

Exercise 2: Using the representation for key pairs described above, draw the box-and-pointer structure for a typical value returned by `generate-RSA-key-pair`.

Exercise 3: The method of sending secure signed messages outlined above says that the sender should first encrypt the message and then sign the result. Would it be better to first sign and then encrypt?

Exercise 4: The procedure `RSA-encrypt` would be much simpler if we were to encrypt each number in the list separately:

```
(define (RSA-encrypt intlist key1)
  (map (lambda (int) (RSA-transform int key1))
       intlist))
```

What would be the analogous `RSA-decrypt` procedure? Why is this simple scheme inadequate for secure encryption?

3. Background for a Programming Assignment

Ministry of Information

To: Ross (the Boss)

From: Rupert

So far we've been pretty successful. I really liked the way you arranged that cattle-futures deal, and the creative accounting by our mole in the Rose Law firm has really done wonders. But I'm getting concerned about the security of our network. My \$4M book deal with the Salamander got out before the optimal moment. I hope we haven't been cracked by the entity in Fort Meade.

Central Control

To: Rupert

From: Ross

You're absolutely right about the need for security. I've gotten in touch with some people I know at Family Values Communications. FVC markets a system that encrypts and authenticates messages using a technique called RSA. The FVC people say they can build an encryption system for the modest fee of \$120M.

Ministry of Information

To: Ross

From: Rupert

\$120 million?!? *You have to be kidding.* That's almost as much as it cost us to replace Gorby with Boris. I contacted Chuck (the Vest) at New England Research and Development (His cover is President of MIT.) to ask his advice. As you know, he helped us arrange the White House mail system.¹⁰ Chuck says he can do the job for us, for a minor consideration. He needs help getting John (the German) installed in the entity in Virginia.

MASSACHVSETTS INSTITVTE OF TECHNOLOGY

Office of the President

Dear Albert and Gerry:

I have received a request of the *highest priority* asking that 6.001's next problem set involve RSA cryptography and digital signatures. Sorry for the rush. I've managed to get some of the code from Family Values Communications, so at least the students won't be starting from scratch. Thanks!

Chuck Vest

¹⁰This is really true. The electronic mail connection to the White House was set up by people at the MIT AI Lab.

4. And now, for the programming assignment!

Begin by loading the code for the problem set, using the Edwin command `M-x load-problem-set`. This will load in Scheme some code that was provided by “friends” at Family Values Communications, and also place this code in an Edwin buffer for you to edit. A listing is attached to this problem set.

To test the code, evaluate

```
(define test-public-key1 (key-pair-public test-key-pair1))
(define result1 (rsa-encrypt "This is a test message." test-public-key1))
```

`Result1` should be the list

```
(209185193 793765302 124842465 169313344 117194397 237972864)
```

`test-key-pair1` is a sample RSA key pair that we have generated for you to test your code with. Keep in mind that punctuation and upper vs. lower case are significant in the test string.

Exercise 1: Unfortunately, the code forwarded to us by President Vest is missing one of the procedures—`RSA-unconvert-list`—required to decrypt messages. Implement this procedure, which takes as arguments a list of integers to decode and a decoding key, and returns a list of integers, undoing the transformation implemented by `RSA-convert-list`. Hint: This procedure is very similar in form to `RSA-convert-list`. If you find yourself doing something much more complicated, then you are barking up the wrong tree—ask for help if necessary.

To test your procedure, try

```
(define test-private-key1 (key-pair-private test-key-pair1))

(RSA-unconvert-list result1 test-private-key1)
```

You should obtain the result

```
(242906196 69006496 213717089 229128819 205322725 67875559)
```

If that works, then you should be able to evaluate

```
(RSA-decrypt result1 test-private-key1)
```

to obtain the original test message (except for some trailing spaces). We’ve also supplied a second key pair for you to work with, which you can obtain by evaluating

```
(define test-public-key2 (key-pair-public test-key-pair2))
(define test-private-key2 (key-pair-private test-key-pair2))
```

Turn in a listing of your procedure, the sample encryption and decryption of the test message, and a sample encryption and decryption (using `test-key-pair1` and `test-key-pair2`) of some messages of your choice.

Exercise 2: Implement the method for encrypting and signing messages described in section 1. Start by specifying a (very) simple data structure called a `signed-message` that consists of a `message` part and a `signature` part. Now define a procedure `encrypt-and-sign` that takes as

arguments a message to be encrypted and signed, the sender's private key, and the recipient's public key. The procedure should encrypt the message, compute a digital signature for it, and combine these to produce a signed message.

As a test, try

```
(define result2
  (encrypt-and-sign "Test message from user 1 to user 2"
    test-private-key1
    test-public-key2))
```

You should obtain a signed message whose message part is

```
(499609777 242153055 12244841 376031918 242988502 31156692 221535122 463709109 468341391)
```

and whose signature part is 15378444.

Now implement the inverse transformation `authenticate-and-decrypt`, which takes as arguments the received signed message, the sender's public key, and the recipient's private key. If the signature is authentic the procedure should produce the decrypted message. If the signature is not authentic the procedure should indicate this. Test your procedures by trying

```
(authenticate-and-decrypt result2 test-public-key1 test-private-key2)
```

to recover the original message. Turn in a listing of your procedures together with a demonstration that they work. (Don't forget to demonstrate that they catch non-authentic signatures.)

Exercise 3: The public key for sending messages to Bill Clinton is defined in the problem set code:

```
(define bill-clinton-public-key (make-key 833653283 583595407))
```

The following public keys are also defined:

```
(define al-gore-public-key (make-key 655587853 463279441))
(define bob-dole-public-key (make-key 507803083 445001911))
(define ross-perot-public-key (make-key 865784123 362279729))
(define hillary-clinton-public-key (make-key 725123713 150990017))
(define tipper-gore-public-key (make-key 376496027 270523157))
(define chuck-vest-public-key (make-key 780450379 512015071))
(define rupert-murdoch-public-key (make-key 412581307 251545759))
(define newt-gingrich-public-key (make-key 718616329 290820109))
```

Yesterday Gingrich received the following message:

```
(510560918 588076790 115222453 249656722 408910590 69814552
 690687967 281490047 41430131 256420885 184791295 75938032
 693840839 663727111 593617709 335351412)
```

The signature was 65732336. (These values are defined in the problem set code as `received-mystery-message` and `received-mystery-signature`.) Fortunately for us, a friend has managed to obtain Gingrich's private key:

```
(define newt-gingrich-private-key (make-key 718616329 129033029))
```

Decrypt the message and identify who sent it.

Exercise 4: Our friends at FVC also sent us a procedure that generates RSA key pairs: the public key and the associated private key. But they are missing the procedure that solves equations of the form $ax + by = 1$. Define this procedure, called `solve-ax+by=1`. It takes two integer arguments a and b whose GCD is assumed to be 1. It returns a pair of integers x and y . Demonstrate that your procedure works by finding integers x and y that satisfy the equation:

$$233987973x + 41111687y = 1$$

Don't forget to check your answer!

If you have correctly defined this procedure, you should now be able to call the procedure `generate-rsa-key-pair` (a procedure of zero arguments) to produce randomly chosen key pairs. Generate a key pair for yourself. Turn in a listing of your `solve-ax+by=1` procedure together with the values you found for the integers x and y . Also turn in a demonstration that your key pair can be used to encrypt and decrypt messages.

Exercise 5: You now have a full implementation of an RSA cryptographic system, complete with facilities for encryption, decryption, digital signatures and signature authentication, and generating new keys. Since the implementation uses such small primes, you should also be able to *crack* the system. In order to crack an RSA system, recall, you must factor the modulus n into its component prime factors p and q . You can do this using the `smallest-divisor` procedure that is included in the code.¹¹ Write a procedure `crack-rsa` that, given a public key, returns the associated private key. Test your procedure using the pairs `test-key-pair1` and `test-key-pair2` to show that it generates the correct private keys, given the public keys. Turn in a listing of your procedure, together with demonstrations that it works.

Exercise 6: Bob Dole would like us to help him trick the Clinton administration into taking unpopular stands. Forge a message from Clinton to Gore, asking Gore to announce that he and Clinton are planning a major tax increase. Show the resulting message, the encryption, and the signature, and demonstrate that the message will be decrypted by Gore using his private key and Clinton's public key.

Exercise 7: Please prepare some appropriate forged messages between various people whose public keys are listed above in lab exercise 3. Demonstrate that these messages will decrypt and authenticate correctly. Be sure to say who the message is (purportedly) from, and to whom it should be sent.

Exercise 8: The RSA system here is easy to crack because the primes are so small: $n = pq$ is the product of two primes each about 5 digits long. You can use the supplied procedure `timed` to see how long it takes `smallest-divisor` to find factors. Evaluating, for example,

```
(timed smallest-divisor 780450379)
```

¹¹When you have found one prime divisor p , the other divisor is $q = n/p$.

will find the smallest divisor of 780450379 and also print how long the computation took in seconds. Check how long it takes to factor n for some of the values produced by `generate-rsa-key-pair`. Based on this data, estimate how long it would take to crack an RSA code if we had used primes that were 50 digits long; 100 digits long. Give your answer in seconds, minutes, days, or years, whichever seems most appropriate.
